(Received: June 5, 2012/Revised: June 18, 2012/Accepted: June 19, 2012)

Abstract: Compared with conventional adsorption-based coloration, the photoreactions of dyes such as photo-copolymerization and photo-crosslinking under UV irradiation can be employed for the coloration of textiles, which can be carried out without salt addition at room temperature. C.I. Reactive Black 5, a homo-bifunctional reactive dye containing two sulfatoethylsulfone groups, is used as a photo-reactive dye for wool fibers. Upon UV irradiation, the photo-reactive dye was grafted onto wool fabrics without photoinitiators. Since the disulfide bonds in the cystine residues of wool can be easily photodecomposed to active thiyl radicals which initiate the polymerization, the dye can be polymerized to an oligomeric dye of a degree of polymerization of 12 or more. The grafted fabrics reached a grafting yield of 2.3% o.w.f. and a color yield (K/S) of 18.2 by the photografting of an aqueous dye concentration of 9% using a UV energy of 25J/cm². Furthermore, the photochemically dyed wool fabric showed higher colorfastness properties to light, laundering and rubbing comparable to conventional reactive dyeing.

Keywords: wool, C.I. Reactive Black 5, UV irradiation, photografting, color yield

1. Introduction

In conventional dyeing methods involving adsorption and diffusion of dyes into fibers, specific classes of dyes should be applied for different types of fibers because the dyes must have strong affinity towards the fibers for good dyeability and color fastness. The intermolecular interactions between the dyes and wool include ionic bond, covalent bond, hydrogen bond, dipolar interaction, and van der Waals force^{1,2}. For example, wool fibers can be dyed with acid, mordant, metal-complex and reactive dyes. Most of the wool dyeings are carried out at the boil with large amount of electrolytes and auxiliaries for good migration and levelness, resulting in inevitable environment unfriendliness including high volumes of wastewater discharge containing unfixed dyes and additives³. Also the heating of aqueous dye solution and drying results in high energy consumption coupled with heavy carbon-emission load. Therefore, new environmentally-friendly dyeing method need to be developed to replace the adsorption-based dyeing which can incorporate little or no electrolyte addition, minimal energy consumption and high fixation.

Also there has been incessant exploration on the 'universal dyeing' which can color all kinds of fibers with same application class of dyes including disperse dyes^{4,5}.

One method is to modify the dyeability of the fibers by engineering the molecular structures of fibers and polymers. The modification includes surface and bulk modification by radiation or chemical treatments. Low-temperature plasma has been confirmed to enhance the hydrophilicity and surface electrostatic properties of wool fabrics as well as the dyeability^{6,7}.

Corona-treated wool fabrics achieved the same or even better colour exhaustion in comparison to conventional pre-treated wool fabric⁸. The wool fabric was treated by UV/ozone significantly increased its wettability and dyeability, which was attributed to the oxidation of the cystine linkage on the surface of the fabric and the formation of free-radical species encouraged dye uptake^{9,10}.

Another method is the grafting of different kinds of functional monomers which can modify dyeability. Grafting is essentially the copolymerisation of a monomer/oligomer to a backbone polymer and new covalent carbon-carbon bonds are formed between graft monomer chains and the polymer surface. The graft polymer

chains on textile surfaces can possess long-term durability due to strong covalent bonds between the grafted chains and substrates¹¹).

For examples, methyl methacrylate (MMA) was grafted onto wool fabric using various initiating systems. Poly(methyl methacrylate) has been grafted onto wool fabric by preirradiation or chemical initiation¹²). The preirradiated grafted wool exhibited a relatively higher dyeing affinity than that prepared by the chemical method. The grafted wool showed an enhancement in dyeability towards some basic dyes of different size and chemical structure. Dimethylaminopropyl methacrylamide (DMAPMA) was grafted onto PET/wool fabrics by continuous UV irradiation under ambient condition¹³). The color yield of the modified PET/wool blend fabrics to wool-reactive dyes increased remarkably due to the formation of covalent bonds between secondary amine in the grafted polymer and reactive groups in the dye molecules.

Until now, there has been no research on the direct photografting of dyes onto the wool fabric. In general, radiation grafting can be initiated with the use of ozone¹⁴), γ rays¹⁵), electron beams¹⁶), plasma¹⁷), corona discharge¹⁸), and UV irradiation^{19,20}). Among them, UV irradiation has been extensively applied for surface graft polymerization of polymers because of facile grafting conditions and less impact on the bulk properties²¹). UV-induced surface graft polymerization exhibits several advantages, such as fast reaction rate, simple equipment, easy exploitation, low temperature treatment, energy saving, environmentally friendliness and may be the most important, the distribution of grafted chains in a shallow region near the surface^{22,23}).

The photo-reactive coloration may realize the universal dyeing without requiring specific intermolecular interactions and affinity of dyes for the fibers. In previous coloration study, C.I. Reactive Black 5 and acrylic acid binary monomers can be easily grafted onto cotton fabric by continuous UV irradiation under ambient condition without salt²⁴).

In the present paper, a novel UV-induced graft polymerization of C.I. Reactive Black 5 onto wool fabric has been disclosed. Significantly, this continuous dyeing is capable of operating at room temperature without auxiliary addition. In addition, the UV-induced grafting mechanism of C.I. Reactive Black 5 was proposed and verified by ¹H NMR, elemental and mass analyses.

2. Experimental

2.1 Materials and chemicals

Plain weave wool (98g/m²) fabrics were used throughout the study. 2-Hydroxy-4²-(2-hydroxyethoxy)-2-methylpropiophenone (Irgacure 2959, Ciba Specialty Chemicals Inc.) was used as a photoinitiator (PI) and Trion X100, a wetting agent, was bought from Yakuri Pure Chemical Co. Ltd (Japan). C.I. Reactive Black 5 (Remazol Black B), supplied by Dystar Textilfarben GmbH & Co., was employed with or without purification.

The chemical structures of the photoinitiator and dye are shown in Figure 1.

2.2 Photografting

Wool fabric was immersed into an aqueous grafting formulation containing dye, PI and Triton X100. Then the impregnated fabric was squeezed to a wet pick up

Figure 1. Molecular structures of (a) Irgacure 2959 and (b) C.I. Reactive Black 5.

of about 90% using a padding mangle.

A UV apparatus enclosing a D-bulb (a Fe doped mercury lamp) of 80W/cm intensity was used for UV irradiation. The main spectral output of D-bulb located in the wavelength range of 350 to 400 nm. UV energy was controlled by adjusting the speed and passing cycles of a conveyor belt. After irradiation, the fabrics were thoroughly extracted first with 2% detergent solution at 60°C for 30min and subsequently with running water to remove the unreacted dye, PI and soluble homopolymer. Grafting yield (G%) was calculated from the following equations respectively:

$$G\% = (W_2 - W_1) / W_1 \times 100$$

where, W_1 is the weight of the original fabric, and W_2 is the weight of UV-irradiated fabric after the extraction.

2.3 Characterization of the photografted wool surface

A 400 MHz ^1H NMR (Avance Digital 400, Bruker) as a solvent was used to characterize the molecular structures of the C.I. Reactive Black 5 before and after UV irradiation using D_2O . Elemental analysis (EA 1110, Mccoy Co.) was used to measure the contents of sulfur, carbon, hydrogen and nitrogen of the C.I. Reactive Black 5 before and after UV irradiation. Mass spectra (LCQ Deca XP MAX, Thermo Electron) of the aqueous formulation containing dye and cysteine before and after UV irradiation were obtained for the identification of the polymerized products.

2.4 The evaluation of coloration

K/S values were calculated from reflectance at λ_{max} measured with a reflectance spectrophotometer (Gretag Macbeth, Coloreye 3100). Color yield was evaluated by Kubelka-Munk equation as the following: $K/S = (1-R)^2 / 2R$ where K is an absorption coefficient, S is a scattering coefficient, and R is the reflectance at λ_{max} . The colorfastness tests to laundering, rubbing and light irradiation of the dyed fabrics were carried out using a Launder-O-meter (Daelim Engineering, Korea), crock meter (Heungshin Engineering, Korea), and Fade-O-meter (Korea Science, Korea) according to KS K ISO 105-C01, KS K 0650 and KS K 0700 respectively.

3. Results and Discussion

3.1 ^1H NMR analysis

The NMR spectrum of C.I. Reactive Black 5 before UV irradiation was shown in Figure 2 (a). The benzene protons of the dye were indicated at the peaks of 3, 4, 5, 5', 6 and 6'. The intense signals of 7 and 8 were assigned to the ethylene protons in sulfatoethylsulfone (SES) groups of the dye. The weak peaks of a, b and c were attributed to pristine vinylsulfone (VS) protons.

In the aqueous formulation containing the dye and cysteine, the cysteine was added as photoinitiator in order to enhance the formation of radicals to simulate the wool cystine. And the weight ratio of dye and cysteine was 5:1. With a UV energy of 25J/cm² (Figure 2 (b)), there appeared new peaks of 3' and 4', which were due to the cleavage of the two C-S bonds (90kJ/mol) in the dye structure under UV irradiation²⁵⁾.

Moreover, the intensity of ethylene protons in SES groups decreased with introduction of some new protons peaks of 11, 12, 13, 14, 15 and 16. The VS groups are expected to be rapidly reacted into four different forms of cyclized [2+2] or linear dimers²⁶⁻³⁰⁾.

Interestingly, poly(vinylsulfone) dyes with high degree of polymerization were also produced by UV irradiation. According to the peak area calculation of the ^1H NMR spectrum, about 55% of the dye was found to be photocyclized or polymerized after UV irradiation. Since Black 5 is a bifunctional reactive dye, the crosslinked and polymerized dye network is expected to be formed most probably. The methine (11) and methylene (12) protons of the polymerized dye units can have many different magnetic environments, influenced not only by *head to head* or *head to tail* configurations but also by the configurational sequences such as *meso* and *racemic* connections. The observed spectra (b insert) seemed to indicate the presence of *meso* and *racemic* configurations. An example of polymerized dye network showing *head-to-tail* configuration was given in Scheme 1. The new peaks 13 and 14 in different configurations may have different chemical shifts, accordingly assigned to 13, 13', 14, 14' and 14". Furthermore, the hydroxyl proton in hydroxyethyl sulfone (HES) group suggested the facile hydrolysis³¹⁾

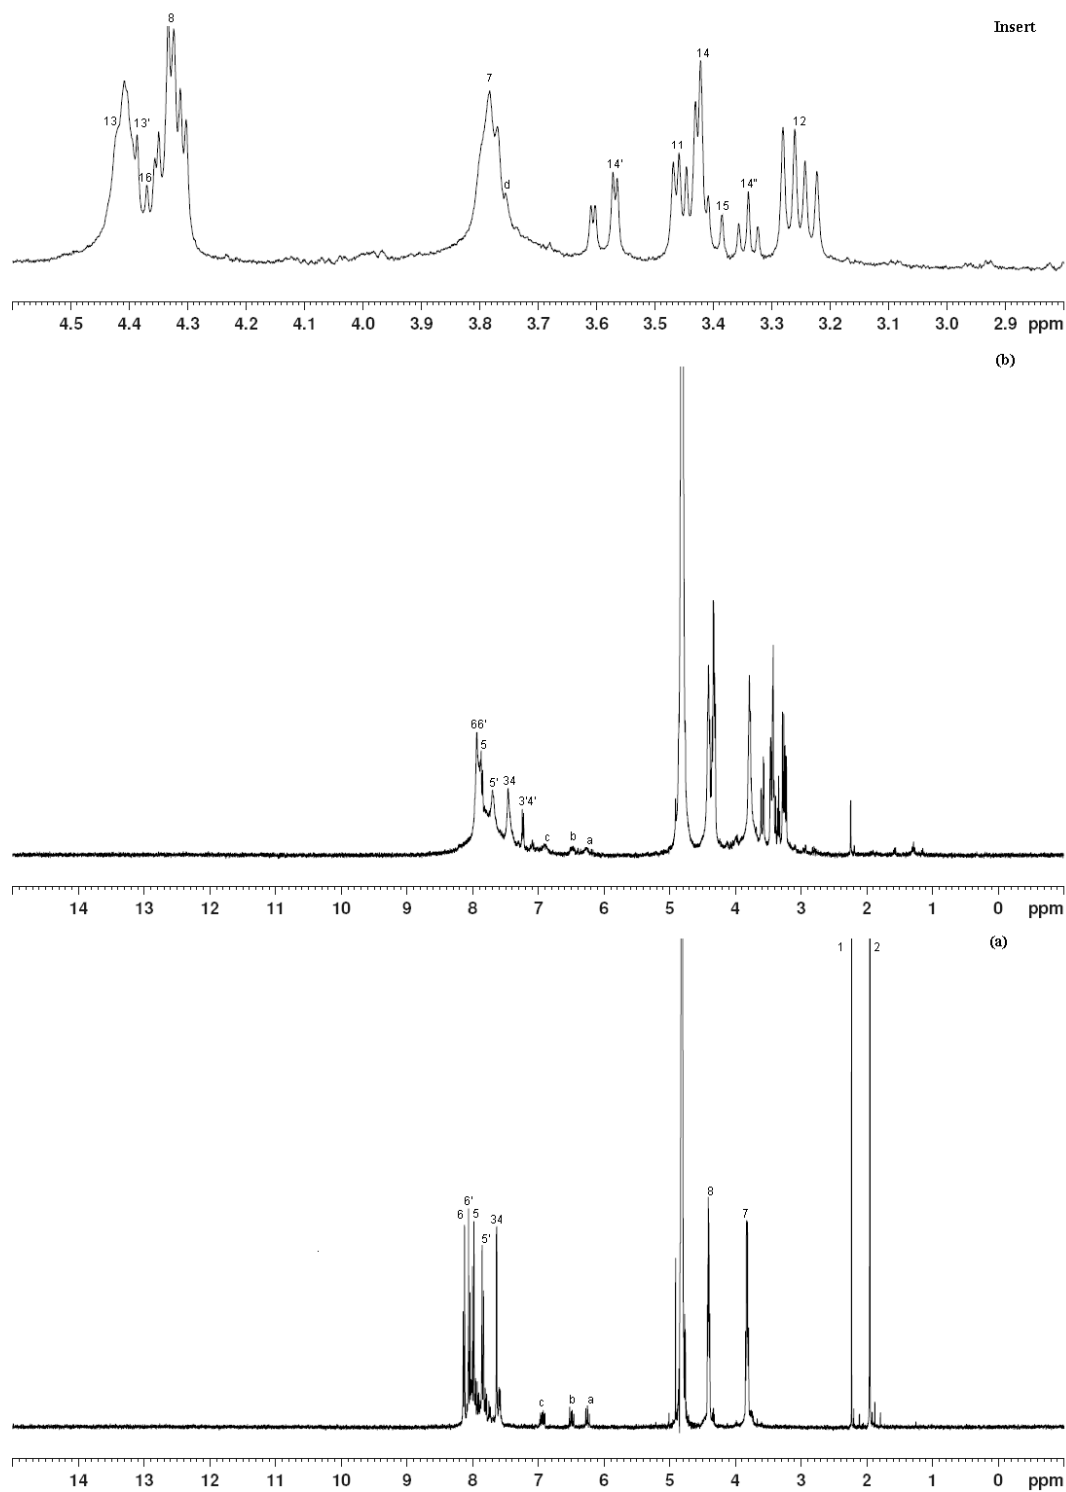

Figure 2. ^1H NMR spectra of the dye (a) and (b) after UV irradiation of $25\text{J}/\text{cm}^2$.

of the dyes under UV irradiation. Therefore, the photopolymerization of the dye can be proved by ^1H NMR analysis. The VS reactive group generated from the SES dye under UV light can be photochemically

converted to VS, which can be cyclized to dimers or polymerized to polymer network initiated by the thiyl radicals from the wool surface. It would be significantly important for the UV-induced coloration for wool.

Scheme 1. Proposed photoreaction of C.I. Reactive Black 5 with cysteine

3.2 Mass analysis

In order to elucidate the mechanism of C.I. Reactive Black 5 polymerization, mass spectroscopic analysis was carried out to identify the polymerized product of the reactive dye. Mass spectra of the aqueous formulation containing dye and cysteine were analyzed before and after UV irradiation. The cysteine was added as a photoinitiator in order to simulate the formation of radicals in the wool. The molecular weight of the dye (M) is 991g/mol. With the lost of four Na⁺ ions, the molecular weight of [M-4Na⁺]/4 is 225g/mol, but the signal corresponding to [M-4Na⁺]/4 was observed at m/z 234 in Figure 3(a), where the difference may be resulted from the hydrated water in the molecular ion. At a UV energy of 5J/cm², the three new signals at the m/z of 170, 381 and 465 were attributed to [M-2SO₃Na-2Na⁺-2H⁺]/4, [M-2SO₃Na-2Na⁺]/2 and [M-2HSO₄Na-2SO₃Na-SO₂CHCH₂-H⁺] respectively because the weak C-S bond (90kJ/mol) can be easily cleaved by the UV irradiation²⁴). Three new signals at the m/z of 527, 611 and 695 were corresponded

to the linked dimers of [M-HSO₄Na-3Na⁺]/3, [M-2HSO₄Na-SO₂CHCH₂-2Na⁺]/2, and [M-2HSO₄Na-2Na⁺]/2 respectively. The peak located at the m/z of 1,562 can be attributed to 2[2M-2HSO₄Na-6SO₃Na-3SO₂CHCH₂-2Na⁺]/2, which is a tetramer.

Under a UV energy of 25J/cm² (Figure 3(c)), the new peaks at the m/z of 1,782 can be assigned to 3[4M-8HSO₄Na-5SO₃Na-7SO₂CHCH₂-3Na⁺]/3, while an m/z of 1,874 corresponded to 3[4M-8HSO₄Na-5SO₃Na-6SO₂CHCH₂-3Na⁺]/3. The other new signal at the m/z of 1,965 can be explained by 3[4M-8HSO₄Na-5SO₃Na-5SO₂CHCH₂-3Na⁺]/3. Since there may be the insoluble fraction in D₂O due to the presence of the crosslinked dye network, it can be concluded that the dye can be photopolymerized to oligomeric dyes containing 12 repeating units or more under the experimental condition.

3.3 UV energy and PI concentration

Figure 4 illustrated that the G% and K/S values increased proportionally with increasing UV energy.

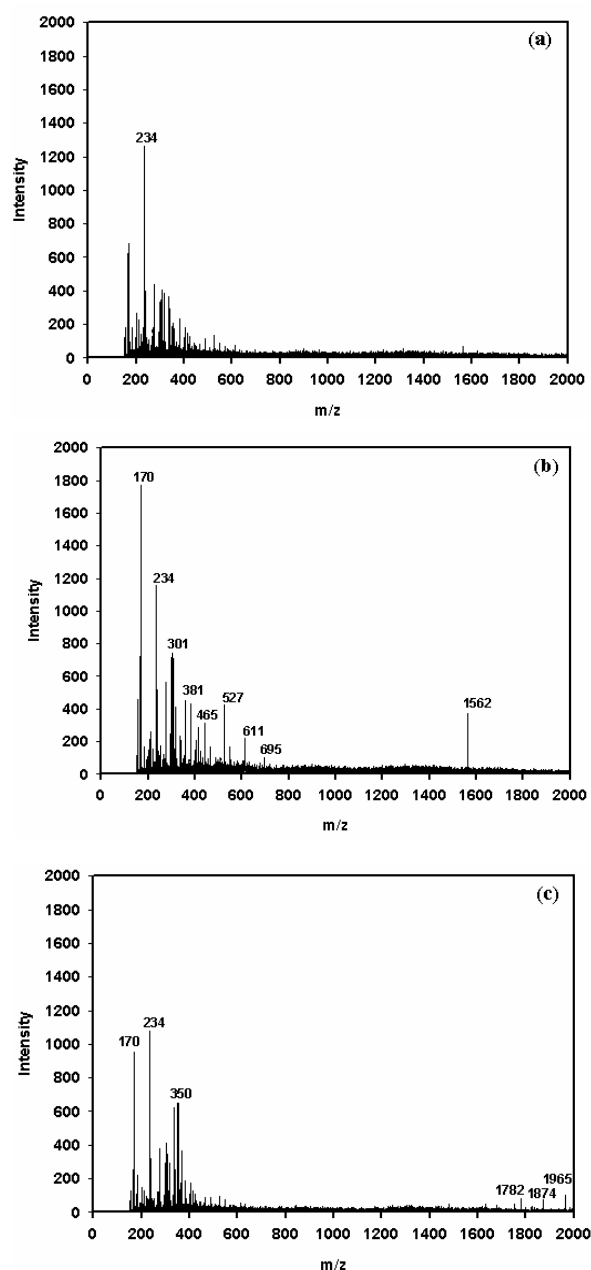

Figure 3. Mass spectra of the dye (a) and after UV irradiation of (b) $5\text{J}/\text{cm}^2$ and (c) $25\text{J}/\text{cm}^2$.

However, the PI concentration did not have significantly effect on G% and K/S (Table 1) probably resulting from the presence of disulfide bonds of the cystine residue in wool capable of producing active free radical under UV irradiation, while the added photoinitiator may promote the homopolymerization rather than graft polymerization. Therefore, the dye can be initiated by thiyl radicals originated from the cysteine³²⁾ and hence the photo-grafting of C.I. Reactive Black 5 onto wool fabric can be carried out without

Figure 4. The effect of UV energy on G% and K/S (photoinitiator concentration: 3%, dye concentration: 9%).

Table 1. The effect of photoinitiator concentration on G% and K/S

| PI concentration (%) | G% | K/S |
|----------------------|-----|------|
| 0 | 2.0 | 16.0 |
| 1 | 2.1 | 16.7 |
| 3 | 2.3 | 18.2 |
| 5 | 2.2 | 17.3 |
| 7 | 2.1 | 17.3 |
| 9 | 2.1 | 17.1 |

(UV energy: $25\text{J}/\text{cm}^2$, dye concentration: 9%, pH 6)

PI under UV irradiation.

Moreover, the G% and K/S increased until a UV energy of $25\text{J}/\text{cm}^2$ and then leveled off. Higher UV energy is expected to increase the number of surface radicals, resulting in higher initiation efficiency for the photopolymerization. Beyond the UV energy of $25\text{J}/\text{cm}^2$, the thiyl radicals cannot be increased more due to the limited cystine content in wool keratin.

3.4 Dye concentration

The increase in dye concentration can promote the rate of the dye polymerization. The graft yield and K/S value increased with increasing dye concentration (Figure 5). However, the dye concentration above 9% may attribute to the blocking of the UV light required for the scission of cysteine, resulting in the dominant homopolymerization of the dyes over the photografting. The photografting mechanism under acidic condition was suggested in Scheme 2. Under UV irradiation the disulfide bonds in the wool cysteine were cut off and

Table 2. Colorfastness of the dyed fabrics to laundering, rubbing and light irradiation

of photo-reactively colored wool fabric were good enough comparable to the conventional dyeing, which made an alternative coloration process of energy- efficiency and environmental friendliness. This novel approach may substantiate ‘universal dyeing’ concept which a single class of photo-reactive dyes can color almost all fibres.
